Leveraging the most recent success in expanding the electrochemical stability window of aqueous electrolytes, in this work we create a unique Li-ion/sulfur chemistry of both high energy density and safety. We show that in the superconcentrated aqueous electrolyte, lithiation of sulfur experiences phase change from a higher-order polysulfide to low-order polysulfides through solid-liquid two-phase reaction pathway, where the liquid polysulfide phase in the sulfide electrode is thermodynamically phase-separated from the superconcentrated aqueous electrolyte. The sulfur with solid-liquid two-phase exhibits a reversible capacity of 1.327 mAh/g of S, along with fast reaction kinetics and negligible polysulfide dissolution. By coupling a sulfur anode with different Li-ion cathode materials, the aqueous Li-ion/sulfur full cell delivers record-high energy densities up to 200 Wh/kg (g of total electrode mass) for >1,000 cycles at ~100% coulombic efficiency. These performances already approach that of commercial lithium-ion batteries (LIBs) using a nonaqueous electrolyte, along with intrinsic safety not possessed by the latter. The excellent performance of this aqueous battery chemistry significantly promotes the practical possibility of aqueous LIBs in large-format applications.

water-in-salt | rechargeable aqueous battery | aqueous sulfur battery | gel polymer electrolyte | phase separation

In the past two decades, rechargeable lithium-ion batteries (LIBs) have revolutionized consumer electronics with their high energy density and excellent cycling stability, and are the state-of-the-art candidates for applications ranging from kilowatt hours for electric vehicles up to megawatt hours for grids (1, 2). The latter applications in large-format present much more stringent requirements for safety, cost, and environmental friendliness, besides energy density and cycle life. The shortcomings of LIB are mostly due to the flammable and toxic nonaqueous electrolytes and moderate energy densities (<400 Wh kg\textsuperscript{-1}) provided by the electrochemical couples currently used (3). Among the various "beyond Li-ion" high-energy chemistries (>500 Wh kg\textsuperscript{-1}) explored currently, the nonaqueous lithium/sulfur (Li/S) battery based on sulfur as a cathode (theoretical capacity of 1,675 mAh g\textsuperscript{-1}) and metallic lithium as an anode seems to be the most practical, as evidenced by the mushrooming literature and significant advances in this system in the past 5 y (4–7). However, commercialization of this system still faces challenges because of severe safety concerns associated with the dendrite growth of metallic Li anode in highly inflammable ether-based electrolytes (8), and the high self-discharge associated with parasitic shuttling of the intermediate polysulfide species. Moreover, the moisture-sensitive nature of the nonaqueous electrolyte would contribute significantly to the cost of the Li/S battery pack due to the stringent moisture-exclusion infrastructure required during the manufacturing, processing, and packaging of the cells. The indispensable accessories for safety and thermal management would further drive up the cost.

Replacement of the nonaqueous electrolyte by its aqueous counterpart is always tantalizing, because it would essentially eliminate safety, toxicity, and at least part of the cost concerns (9–11). In particular, wide electrochemical stability windows (>3.0 V) comparable to those of nonaqueous electrolytes have been recently demonstrated by water-in-salt (WiS) and water-in-bisalt (WiBS) electrolytes. With water molecules still far outnumbering that of Li salts, this class of completely nonflammable WiS and WiBS electrolytes realized a dramatic improvement in safety, while placing many Li-ion and even beyond Li-ion chemistries within the reach of aqueous electrolytes (12, 13). Historically, it has been very challenging to use elemental sulfur as the cathode material in aqueous electrolytes, primarily because of the high solubility of short-chain lithium polysulfide (Li\textsubscript{2}S\textsubscript{y}, y < 6) and Li\textsubscript{2}S in aqueous media, and the strong parasitic shuttling reaction occurring thereafter (14). A compromise approach used aqueous solution of lithium polysulfide as the liquid active cathode (catholyte), but only 61% of the theoretical capacity was accessed in the Li\textsubscript{2}S\textsubscript{y}/Li/S redox couple (15–17). The hydrogen evolution in this aqueous system and the side reaction between the Li\textsubscript{2}S\textsubscript{y}/Li/S and H\textsubscript{2}O have to be suppressed to achieve high coulombic efficiency. A Li metal anode can be used, but only after a dense Li-ion-conducting ceramic layer is engineered on the Li surface to prevent Li dendrite formation and prevent the reaction of Li anode from aqueous catholyte (17).

However, the reported electrochemical stability windows of the superconcentrated aqueous electrolytes (WiS, WiBS) were >3.0 V, with cathodic and anodic limits located in the vicinity of ~1.9 V and ~4.9 V vs. Li, respectively. This window would comfortably envelop the lithiation/delithiation reactions of high-capacity sulfur as an anode coupled with a lithium-ion intercalation cathode in the superconcentrated aqueous electrolyte creates a unique Li-ion/sulfur chemistry, realizing the highest energy density ever achieved in aqueous batteries, along with high safety and excellent cycle-life. Mechanism investigation finds that the reversible sulfur lithiation/delithiation in such an aqueous electrolyte proceeds with fast kinetics that significantly differ from that in nonaqueous systems, whereas polysulfides’ insolubility in such an aqueous electrolyte essentially eliminates the parasitic shuttling. The excellent performances of Li-ion/sulfur cells not only find an application of “water-in-salt” electrolyte for beyond Li-ion chemistries, more importantly, an alternative pathway is provided to solve the “polysulfide shuttling” that has been plaguing the sulfur chemistries in nonaqueous electrolytes.

sulfur materials at the anode side and transition metal oxide materials at the cathode side. The electrochemical coupling of a sulfur anode and an intercalation cathode would thus create a new cell chemistry without Li metal, which is based on Li⁺ intercalation/deintercalation at the cathode, and conversion reaction of sulfur species at anode. This Li-ion/sulfur chemistry (Li⁺/S) can deliver theoretic energy densities up to 260 Wh·kg⁻¹, and combines the high capacities of a cheap sulfur anode and mature LIB cathode, as well as the intrinsic safety of an aqueous electrolyte. Additional benefits include substantial cost reduction at the battery module or pack level, via elimination of moisture-free infrastructures for processing and fabrication, and the possible simplification of the safety management.

In this work, we demonstrate this highly reversible aqueous Li⁺/S chemistry using a simple sulfur/carbon composite as the anode and LiMO (LiMn₂O₄ and LiCoO₂) as the cathodes. Through in situ and ex situ spectroscopic means during electrochemical reactions, the unique lithiation/delithiation mechanism of sulfur in WiBS electrolyte was revealed to proceed reversibly in a solid-liquid phase. A total of 80% (1.327 mAh·g⁻¹) of sulfur theoretical capacity (1.675 mAh·g⁻¹) was accessed with excellent reversibility, as evidenced by capacity retention of 86% for 1,000 cycles. This outstanding performance is attributed to the phase separation of S/poly sulfide solid-liquid phase from high-concentration aqueous electrolytes, where the liquid WiBS electrolyte functions in a similar manner as solid electrolyte in isolating the polysulfide species generated at anode from LiMO cathodes, thus eliminating the parasitic shuttling that have been plaguing the non-aqueous Li/sulfur chemistry. When the sulfur anode was paired with typical LiB cathode materials like LiMn₂O₄ or high-voltage LiCoO₂, energy densities of 135~200 Wh·kg⁻¹ were delivered at full cell level. These findings suggest that safety, cost, environmental considerations, and energy density requirements could be simultaneously achieved by the aqueous Li⁺/S battery for large-scale applications, such as smart-grid storage or automotive power systems.

Results

Electrochemical Behaviors of Sulfur in WiBS Aqueous Electrolyte. The electrochemical behaviors of a sulfur–Ketjen black (S-KB) carbon composite electrode in WiBS electrolyte and in typical organic electrolyte were investigated with cyclic voltammetry. WiBS electrolyte was obtained by dissolving two Li salts, lithium bis(trifluoromethane sulfonyle)imide (LiTFSI) and lithium trifluoromethane sulfonate (LiOTF) at 21 and 7 mol·kg⁻¹, respectively, in water at 25 °C. Using two lithium salts allows us to circumvent the solubility limit of each single lithium salt in water, hence reaching the highest salt concentration possible (13). The extremely high concentration therein provides an expanded stability window thanks to the formation of a dense and protective solid electrolyte interphase (SEI) and the reduced water activity (13); it is also a key to manage stable phase-separation of liquid reaction intermediate and liquid electrolyte, which will be fully discussed below. Reversible lithiation/delithiation reaction of sulfur in this 28-mol·kg⁻¹ electrolyte was observed at 2.46 and 2.65 V, respectively (Fig. 1A). Although the potential for hydrogen evolution at pH ~7.0 is known to be ~2.63 V vs. Li, the SEI suppresses the reduction of water molecules down to the potential of ~1.9 V, hence making the reversible lithiation/delithiation reaction possible. Upon closer comparison with the well-known redox processes of sulfur in nonaqueous media at 2.1~2.4 V (Fig. 1A, black dashed line) (19), an apparent positive shift of ~0.3 V occurred in the aqueous solution which has been observed previously and attributed to the high Li salt concentration in WiBS electrolyte (12). More noticeable is the drastic change from the characteristic two-stage lithiation process in nonaqueous media to a seemingly single-stage redox process in aqueous media, as well as the much reduced potential hysteresis in the latter. Such changes are more visually obvious in the corresponding voltage profiles obtained in galvanostatic mode (Fig. 1B), where a single, well-defined plateau at ~2.5 V represents the discharge/charge of S-KB in the WiBS electrolyte, significantly differing from the two plateaus found at ~2.3 and 2.1 V in nonaqueous electrolyte (20). Apparently, the electrochemical reaction of sulfur in this superconcentrated aqueous electrolyte proceeds via a new reaction mechanism that is hitherto unknown. What we see in Fig. 1 should be a previously unobserved aqueous sulfur chemistry.

The typical two-plateau discharge curve obtained in nonaqueous media has been attributed to the solid-to-liquid (sulfur to dissolved high-order polysulfide) reaction, and liquid-to-solid (high-order polysulfides to low-order sulphide solid) reaction (21–23). The single-stage discharge plateau in WiBS electrolyte, however, suggested that the redox processes of sulfur undergo a single solid–liquid reaction, which proceeds with ultrafast kinetics; this is also consistent with the finding of Li,S product formed during early charging, as discussed hereafter. As a result, a reversible capacity of 1,338 mAh·g⁻¹ was achieved based on the sulfur mass at a current density of 335 mAh·g⁻¹ (0.2C), which is 80% of the theoretical capacity and comparable with the best results achieved in nonaqueous electrolyte (4).

Reaction Mechanism of Sulfur Anode in WiBS Electrolyte. To fully understand this sulfur chemistry in WiBS electrolyte, we used in situ Raman spectroscopy to monitor the transformation of polysulfide species in the S-KB anode at different states of charge (SOC) during the third charge of an S-KB/LiMn₂O₄ full cell (Fig. 2A). The fully discharged (delithiated) S-KB anode (SOC = 0%, corresponding to the fully charged state of sulfur when used as cathode in nonaqueous electrolyte) showed conspicuous peaks (indicated by yellow region in Fig. 2A) corresponding to elemental sulfur (α-S₈) at 81, 151, 217, and 470 cm⁻¹ (24). Based on the normalized intensity ratio, the estimated amount of α-S₈ exponentially declines to nearly zero before the SOC reaches 25%, suggesting a surprisingly rapid and full consumption of S₈ by lithiation (Fig. 2C). A sharp peak at 339 cm⁻¹, which was assigned to the long-chain polysulfide species Sₓ⁻²⁻ (25, 26), appeared at SOC = 25% but disappeared after SOC = 75%. Meanwhile, a small peak at 234 cm⁻¹, which was attributed to the bending mode of Sₓ⁻²⁻, gradually grew after SOC = 25% during charge (27). At the final stage of charge (SOC = 100%), a Li₄S peak located at 371 cm⁻¹ appeared. These results clearly show the very rapid procession from elemental sulfur to long-chain polysulfides and then to the fully lithiated form Li₂S (i.e., S₈ → long chain LiₓSₓ → short chain LiₓS → Li₂S). The fast kinetic drastically differs from the reduction of sulfur in nonaqueous media. In the aqueous media, an obvious lift-up occurs in the range of 65–300 cm⁻¹ (Fig. 2A) with a peak at 80 cm⁻¹ for SOC ≥ 50%. To investigate these peaks further, the Raman spectra of
element sulfur powder, pure Li$_2$S powder, Li$_2$S$_2$ in aqueous solution, and WiBS electrolyte were analyzed (SI Appendix, Fig. S1). The peaks in the range of 65–300 cm$^{-1}$ with a peak at 80 cm$^{-1}$ for the S-KB anode were well fitted to the Raman spectra of water-solvated polysulfide mixture (Li$_2$S$_2$, purple area). Therefore, the Li$_2$S$_2$ manages to extract H$_2$O from WiBS electrolyte to form a Li$_2$S$_2$-anolyte, which is immiscible with the bulk WiBS electrolyte (Fig. 2D). Note that the dissolved lithium polysulfide (LiPS) only shows a wide peak at 80 cm$^{-1}$. Hence, sharp peaks for S$_{x^-}$ at SOC $= 25\%$ and for S$_{2^-}$ at SOC $= 75\%$ can only be attribute to solid phase of LiPS. A more direct observation of solid–liquid mixed polysulfide phase was confirmed by replacing an S-KB anode with sulfur coated on aluminum mesh (denoted as S@Al hereafter) that was horizontally placed on the top surface of WiBS electrolyte. The Raman spectra of the charged S@Al electrode showed individual traces of both liquid and solid polysulfide (SI Appendix, Fig. S2). This observation unambiguously reveals that the reaction intermediate (polysulfide) exist in both solid and liquid phase, where the liquefied polysulfides would have been confined by pore structure of carbon matrix and hence phase separated from WiBS in our full cells. Further confirmations of solid–liquid mixed phase of S-KB came from the electrochemistry performances of the washed S-KB at different SOC (SI Appendix, Fig. S3). After charging to states of 50%, 75%, and 100%, the S-KB electrodes were disassembled and washed using anhydrous dimethoxyethane (DME) for several times to remove the liquid polysulfides, and then reassembled to measure the residual low-order solid polysulfides. After removing liquid phase and long-order LiPS intermediate, the remaining low-order solid polysulfides still can provide $>70\%$ of initial capacities. In diluted aqueous solutions, the long-chain species Li$_2$S$_x$ (x $> 4$) are considered insoluble due to their relatively less-polar nature, whereas the short-chain species Li$_2$S$_x$ (x $\leq 4$) are highly soluble (over 4 M) due to their higher ionic nature (15, 17). However, both species become insoluble in WiBS electrolyte due to the high lithium salt concentrations. Molecular dynamics (MD) simulations of Li$_2$S$_2$ and Li$_2$S$_3$ in WiBS electrolyte revealed that these polysulfides severely aggregate, resulting in obvious domain formation in WiBS as shown in Fig. 2E and F, with shorter polysulfide yielding more pronounced aggregation. Quantum chemistry calculations predicted higher stability of Li$_2$S$_2$ vs. Li$_2$S$_3$ in aqueous environment as discussed in SI Appendix. Preferential stability of shorter polysulfide Li$_2$S$_2$ vs. Li$_2$S$_3$ together with their stronger aggregation and separation is consistent with the experimentally observed phase separation of polysulfides in WiBS electrolyte. MD simulations also show that the short-chain Li$_2$S$_x$ (x $\leq 4$) can indeed extract water molecules from the superconcentrated WiBS electrolyte until reaching equilibrium with WiBS, forming a mixed solid and liquefied anolyte, which is not miscible with the bulk WiBS electrolyte. Hence, the lithiation state of the sulfur anode in WiBS electrolyte should maintain solid–liquid mixed phase, in accordance with the previous electrochemical behavior. Thanks to the immiscibility of saturated Li$_2$S$_x$ (x $< 4$) anolyte with WiBS electrolyte, the parasitic shuttle reactions of the polysulfides that have been plaguing the nonaqueous Li/S chemistry are effectively suppressed.

X-ray photoelectron spectroscopic (XPS) analysis was also conducted on the S-KB anodes retrieved from the full cells at different SOCs of the third charge (Fig. 2B). For clarity, only the 2p$_x$ component of the S 2p$_2$/$2p_3$ doublet was analyzed. Because the peaks of the binding energy over 166 eV are dominated by the contributions from LiFTSi and LiOTf salt anion residuals, as demonstrated in SI Appendix, Fig. S4, only the spectra in the range of 158–166 eV were selected to fit the 2p$_3$ of S$_{x^-}$, S$^{2-}$, and S$^{3-}$ (Fig. 2B, 29, 28). At SOC $= 0\%$, only S$_{8}$ (164.4 eV) was observed, whereas polysulfide species S$_{x^-}$ ($8 \geq x \geq 2$) appeared during lithiation, which were fitted with S$^0$ at 164.0 eV and S$^{1-}$ at 162.2 eV, respectively. In the chain structure of S$_{x^-}$ species, the two terminal sulfur atoms at both ends bear a formal charge of $-1$, with several bridging sulfur atoms in the middle bearing a formal charge of zero. The average oxidation states were thus determined by the ratio of terminal/bridging sulfur peaks, leading to an average lithium polysulfide formula approximately equal to Li$_2$S$_{x^-}$ (SOC $= 25\%$), Li$_2$S$_3$ (SOC $= 50\%$), and Li$_2$S$_5$ (SOC $= 75\%$), respectively (red line in Fig. 2C). Interestingly, the XPS spectra showed that Li$_2$S$_x$ represented by S$^{2-}$ at 160.7 eV, was generated immediately upon lithiation. In the nonaqueous Li–S battery, however, this fully lithiated form would only appear in the very late or even the last stage of lithiation, due to the slow reaction kinetics (6, 20). The early appearance of Li$_2$S in WiBS electrolyte confirms the rather fast kinetics for the lithiation reactions, and is consistent with a relatively flat charge–discharge profile. At the end of the lithiation (SOC $= 100\%$), Li$_2$S$_3$ expectedly becomes the dominant species (72%), in excellent agreement with the 79% of the theoretical capacity obtained previously. Meanwhile, XPS spectra also confirmed the formation of a LiF-rich SEI on anode surface, with a conspicuous change in F 1s peaks before and after 20 lithiation cycles. Similar conclusions can be drawn from high-resolution TEM images (SI Appendix, Figs. S5 and S6).

In summary, the S-KB composite in WiBS electrolyte seemed to follow a similar lithiation pathway to that in nonaqueous electrolyte, represented by the formation of predominant Li$_2$S$_6$, Li$_2$S$_5$, Li$_2$S$_3$, and Li$_2$S XPS peaks (8, 30), but with unprecedented fast kinetics. Short-chain LiPS species (Li$_2$S$_x$, x $< 6$) have been considered soluble in aqueous media (15), as confirmed by the formation of water-solvated species detected in the Raman spectra for lithium polysulfide. MD simulations also predict that...
both solid Li₂S₂ and Li₃S₄ can take very small amount of water from WiBS electrolyte to form solid–liquid mixed semianolyte due to limited free-water in WiBS and large amount of Li₂S₂/Li₃S₄ (SI Appendix, Fig. S21). However, using both in situ Raman and mass spectra, we found that only a trace amount of liquid lithium polysulfide (<71 ppm) was observed to diffuse into the bulk electrolyte (SI Appendix, Figs. S7 and S8). SEM images and corresponding energy-dispersive X-ray spectroscopy of sulfur demonstrated little change in surface morphology of the S-KB anode (SI Appendix, Fig. S9). All these findings, along with the excellent electrochemical behavior, converged to one conclusion that the extremely high concentration of LiTFSI and LiOTf should be nearly saturated, but inevitably cross-over of trace water still occurs at the interface, causing such disproportionation reaction.

These lithium polysulfide solutions were mixed with a 28-mol% water content (Fig. 2D) and LiTFSI/LiOTf should be nearly saturated, but inevitably cross-over of trace water still occurs at the interface, causing such disproportionation reaction. On both sides of the interface, Li₂S₂ and LiTFSI/LiOTf should be nearly saturated, but inevitably cross-over of trace water still occurs at the interface, causing such disproportionation reaction.

Poly sulfides dissolved in aqueous solutions have a tendency to hydrolyze rapidly and release hydrosulphide anion HS⁻ and/or H₂S, which would be hazardous from both battery performance and safety/environment considerations (17). This side reaction was found to be effectively suppressed in WiBS electrolyte system, because of the low activity of water molecules that are tightly bound by the high population of cations and anions. Quantum chemistry calculations also showed that such H-transfer reaction is energetically unfavorable for Li₂S₂ in WiBS, as shown in SI Appendix, Figs. S18–S20.

**Electrochemical Performance of S-KB/LiMn₂O₄ Full Cells.** A full cell of the previously unobserved Li⁺/S chemistry was constructed using the S-KB anode coupled with a LiMn₂O₄ cathode (SI Appendix, Fig. S13A) in WiBS electrolyte, and its electrochemical behavior was evaluated at different current densities (Fig. 3A). The cathode/anode capacity ratio was set at 1.03:1, and the areal sulfur loadings in S-KB anode was set at a high value of ~8 mg.cm⁻² (31). Remarkably, at a slow rate of 0.2C (discharge/charge of full theoretical capacity in 5 h), the cell being cycled between 2.2 and ~0.5 V exhibited a single discharge plateau with an average voltage of 1.60 V, delivering a discharge capacity of 84.40 mAh.g⁻¹ of total electrode mass (i.e., 1,327 mAh.g⁻¹ of sulfur mass) or an areal capacity of 10.6 mAh.cm⁻². The energy density was conservatively estimated to be ~135 Wh/(kg of total electrode mass), which represents a marked improvement not only over all conventional aqueous Li-ion systems (<75 Wh.kg⁻¹) (9, 11), but in particular also over what was achieved by the high concentrated aqueous electrolytes (12, 13, 18). At a rate five times higher (1C), the capacity dropped only slightly, to 68.24 mAh.g⁻¹, reflecting the fast kinetics of the cell reactions.

To examine the reaction kinetics of S-KB anodes, we performed galvanostatic intermittent titration experiments (GIITT) (Fig. 3B) on an S-KB/LiMn₂O₄ full cell with the capacity of the LiMn₂O₄ cathode being in excess by five times to that of the S-KB anode. A constant current (0.1C) was applied as short pulses, between which the system was allowed to relax to quasi-equilibrium (Materials and Methods). Remarkably, a reversible capacity close to the theoretical value of sulfur (1,667 mAh.g⁻¹) was achieved during the first cycle under this quasi-equilibrium condition, which cannot be achieved in nonaqueous systems (32, 33). Moreover, the gap between the potential at the end of each pulse (polarization potential, as indicated by the black line in Fig. 3B) and the potential at the end of each relaxation (quasi-equilibrium potential, as indicated by the red line) were consistently low at 30–80 mV during most of the charge/discharge processes, except at the end of charge/discharge due to the increase in concentration polarization. This remarkably small overpotential further confirms the fast liithiation/delithiation kinetics of the S-KB anode in WiBS electrolyte. In sharp contrast, the lithiation process in typical nonaqueous electrolytes based on 1,3-dioxolane and dimethoxyethane normally undergoes three distinct stages with varying kinetics, which correspond to phase...
changes from solid \( \text{S}_0 \) to soluble \( \text{S}^{2-} \) species \((x > 4)\) followed by isolated solid \( \text{LiS}_x \) (\( x = 2 \) and 1) \((32)\), accompanied by much higher potential hysteresis. A single-potential plateau similar to this work has been observed in the Li/S cell with a solid-state electrolyte \((34)\), but still with much higher potential. The aqueous sulfur chemistry described in this work provides an avenue to exploit this cheap and energy-dense cathode material.

**Cycling Performance of S-KB/LMO Full Cells.** The cycling stability has always been an issue plaguing nonaqueous Li/S batteries, whose capacity fades rapidly due to the dissolution of polysulfide intermediates and the parasitic shuttling reactions thereafter, which result in self-discharge within the cell as well as continuous loss of active materials \((30)\). However, in the 28-mol-\( \text{kg}^{-1} \) WiBS electrolyte, they are effectively suppressed because of the very limited free-water in WiBS and the phase separation between polysulfides and WiBS. The full Li-ion/sulfur cell in 28-mol-\( \text{kg}^{-1} \) WiBS electrolyte showed good cycling stability \((\text{Fig. 3C})\) due to the immobilization of the polysulfide species. However, a capacity decay of 22% still occurs over 200 cycles at 1C rate, indicating that the disproportionation reaction of lithium polysulfides still prevailed over the time due to cross-over of trace water at the interface. This side reaction slowly created elemental sulfur particles during repeated charge/discharge, leading to a major loss of active material \((\text{SI Appendix, Figs. S11C and S12A})\).

Further efforts were made to mitigate the generation and cross-over of elemental sulfur particles by immobilizing them in a “solidified” WiBS electrolyte with the formation of a polymeric gel. A hydrophilic polymer polyvinyl alcohol \((\text{PVA})\), which has been widely used as a matrix in solid-state supercapacitors \((35, 36)\), was introduced into the WiBS electrolyte to form a hydrogel \((\text{SI Appendix, Fig. S14A and B})\). Unexpected high solubility of PVA \((\text{mass ratio of PVA to water} > 0.8:1)\) suggested that PVA chain with abundant hydroxyl groups, which also possess solvation power, must have interacted with lithium salts. The FTIR \((\text{SI Appendix, Fig. S14C})\) of this gel polymer electrolyte \((\text{GPE})\) is almost identical to its parental aqueous electrolyte, and there is also little difference in ion conduction as well as interphasial behavior between the GPE and its parental aqueous electrolyte \((\text{SI Appendix, Fig. S14D})\), as evidenced by almost identical electrochemical impedance spectroscopy in the course of 50 cycles \((\text{SI Appendix, Fig. S15})\). The S-KB/LiMn\(_2\)O\(_4\) in this 28-mol-\( \text{kg}^{-1} \) WiBS-GPE exhibited almost identical charge/discharge profiles as that of 28-mol-\( \text{kg}^{-1} \) WiBS liquid electrolyte \((\text{SI Appendix, Fig. S14F})\). The hydrophilic polymer matrix, however, is expected to further interact with the lithium salts dissolved in WiBS, and repels the polysulfide anions, providing a chemical barrier to the sulfur loss into the bulk aqueous electrolyte \((\text{SI Appendix, Fig. S12B})\). With PVA polymer bonding with both water molecule and Li salts, the cross-over of trace water was significantly minimized, and the disproportionation reaction of LiPS essentially eliminated. This approach effectively maintains the sulfur in an active electrochemical state, thus significantly reducing capacity decay to 7% in the first 200 cycles at 1C. More importantly, after 1,000 cycles at 1C, the capacity still retained 86% of its initial value, corresponding to a very small capacity decay of 0.014% per cycle \((\text{Fig. 3C})\). This low fading rate is the best observed among all lithium/sulfur batteries, either nonaqueous or aqueous \((5, 7)\). Even at a low charge/discharge rate of 0.2C, which has always been a challenge not only for the Li/S system but for all aqueous systems, the capacity decay was still only 9% after 100 cycles \((\text{Fig. 3D})\). During the SEI formation on the anode surface in the initial several cycles, Coulombic efficiency quickly increased from 92.49% in the first cycle, to 95.4% in the second cycle, then to 99.95 at the 30th cycle, and eventually reached ~100% after 40 cycles. Such high Coulombic efficiency ensures the long cycle stability. The effectiveness of this strategy in suppressing the side reaction was also evaluated by measuring the self-discharge rate of a Li\(^+\)/S cell at 100% SOC \((\text{SI Appendix, Fig. S16})\). As expected, a pronounced increase in retained discharge capacity was observed after a 24-h open-circuit voltage relaxation.

**High Energy Density S-KB/HV-LiCoO\(_2\) Full Cells.** We have already constructed a unique Li\(^+\)/S battery based on this unique sulfur chemistry, which, with sulfur coupled with a LiMn\(_2\)O\(_4\) cathode in WiBS electrolyte, achieved a gravimetric energy density of 135 Wh/(kg of total electrode mass) and a volumetric energy densities of ~384 Wh/(L of total electrode and electrolyte). It should be noted that the energy density of the S-KB/LiMn\(_2\)O\(_4\) cell is limited by the LiMn\(_2\)O\(_4\) due to its low potential and moderate capacity. For practical applications where high energy density is desired, cathode candidates with higher specific capacity and redox potential should be further explored \((\text{Fig. 44})\). For instance, high-voltage LiCoO\(_2\) (HV-LiCoO\(_2\)) with a capacity of 170 mAh g\(^{-1}\) \((\text{SI Appendix, Fig. S13B})\) would make a better cathode in this aqueous sulfur battery \((37)\), raising the energy density to an unprecedentedly high level for aqueous batteries. Indeed, such a full cell based on HV-LiCoO\(_2\) cathode and S-KB anode delivered a stable discharge capacity of 119 mAh/g of total electrode mass with an average voltage of 1.64 V at 0.2C, leading to a gravimetric energy density of 195 Wh/(kg of total electrode mass) and a volumetric energy density of ~454 Wh/(L of total electrode and electrolyte volume; \text{Fig. 4B}). With further optimization and engineering in cell design, the theoretical...
value of 267 Wh kg\(^{-1}\) for the sulfur/HV-LiCoO\(_2\) couple (Fig. 4C) could be eventually achieved. This highest value of energy density ever achieved in aqueous batteries is already approaching the commercial LIB chemistry (SI Appendix, Table S2), along with much superior safety.

As an overview of the state-of-the-art, in Fig. 4C we compared our aqueous Li\(^+\)/S batteries against other successful aqueous systems reported previously. In most cases, energy densities for aqueous systems were below 78 Wh kg\(^{-1}\) (10, 38-40). The high-voltage aqueous Li-ion systems achieved in WiS electrolyte can deliver higher-energy density between 84 and 101 Wh kg\(^{-1}\) (12, 13), although Yamada et al. (18) raised this value to ∼130 Wh kg\(^{-1}\) by coupling lithiated titanate with LiCoO\(_2\). Even higher energy density (183 Wh kg\(^{-1}\) based on the weight of active electrode materials) became possible when Zn\(^{2+}\) and Li\(^+\) chemistries are hybridized (41). It should be noted that the value of ∼200 Wh kg\(^{-1}\) obtained from S/LiCoO\(_2\) couple is already higher than some nonaqueous Li-ion batteries, e.g., LiMn\(_2\)O\(_4\)/LiTi\(_2\)O\(_3\)\(_2\) (160 Wh kg\(^{-1}\)).

**Conclusion**

We demonstrated a unique sulfur chemistry in superconcentrated aqueous electrolyte, which delivers a close-to-theoretical capacity and fast reaction kinetics. We believe that, with the judicious choice of proper cathodes with higher capacities or potentials, the energy densities of the intrinsically safe and green aqueous rechargeable batteries could be further increased, eventually challenging the commercial nonaqueous LIBs (theoretical energy density of 150–400 Wh kg\(^{-1}\)), especially in applications where the needs for safety, low cost, and low toxicity outweigh those for high energy and power densities. Further efforts should be focused on cost reduction of WiBS electrolyte, making the Li-ion/sulfur battery closer to practical applications. The promising approaches might include alternative low-cost salts with the potentials to form similar phase separation, together with optimized cell engineering.

**Materials and Methods**

S-KB composite was obtained by thermal treatment to incorporate sulfur into the porous matrix. The electrodes were fabricated by compressing the mixture of active material powder, carbon black, and polytetrafluoroethylene (PTFE) on metal grid current collectors. WiBS aqueous electrolytes were prepared by dissolving 21 mol kg\(^{-1}\) LiTFSI and 7 mol kg\(^{-1}\) LiOTf salts in water. Aqueous gel electrolytes were prepared by further dissolving 10 wt % polyvinyl alcohol in the liquid WiBS electrolyte at 95 °C. More details of the materials used and methods followed are provided in SI Appendix.
